Abstract

An equation for the reduced density matrix which describes a free particle, that is interacting with a linearly dissipative medium, is derived using the total Hamiltonian, and without resorting to any artificial model. A Master equation is also obtained for the dissipative medium. The theory erases the notion of the reservoir. It is shown that the dynamical interaction with the medium is not completely determined by the friction constant (or the corresponding fluctuation-dissipation relation). Unexpectedly, through the density-density correlation, the longitudinal dielectric function is shown to play a critical role.

The process of dissipation is almost the antithesis of unitary evolution of the wavefunction, and therefore a quantum description of even the simplest quantum system (that of a free particle) interacting with a dissipative medium has turned out to be a formidable problem. In fact, and as is clear from recent publications [1] – [5], there is still no agreement on the equation of motion for the reduced density matrix that describes the particle. The main problem has been the derivation of a suitable Hamiltonian that describes the whole system. So far, no one has found operators that can simultaneously a) describe the essential features of the dissipative medium, b) satisfy a commutation relationship, and c) be used to construct that part of the Hamiltonian that describes the interaction with the free particle. Consequently, the dissipative medium has often been modeled as a collection of harmonic oscillators (or similar entity) with features prescribed by the fluctuation-dissipation theorem [6] – – – [14]. – – –

Among the many conditions on the equation for the reduced density matrix, two of the most difficult to fulfill have been a) an equation that is valid when quantum fluctuation is larger than thermal fluctuation, and b) an equation that ensures positivity of the density matrix. It was demonstrated that in order to describe quantum Brownian motion the probability diffusion coefficient typically features a time dependence, and does not vanish at zero temperature [9], [12]. However those works were criticized because positivity of the density matrix was not guaranteed. On the other hand, in works where a term was added to the standard Master equation in order to ensure a positive semidefinite density matrix [15], [4], [2], none of the equations can really describe quantum Brownian motion because the diffusion coefficient vanishes at zero temperature, and symptomatically it is not time-dependent. As will become clear, a key fragment of the riddle of Brownian motion, as well as the shortcomings of all previous approaches, originate in the certainty of the fluctuation-dissipation relation for the friction coefficient. In the following discourse, I present for the first time a description of Brownian motion that does not rely on a collection of harmonic oscillators (or similar) model for the lossy medium. A complete Hamiltonian is derived and used.

The particular system of interest — a current driven RC circuit —, which is identical to a free particle driven by an external force, is shown in figure 1. In the absence of a resistor, the system is well described by the charge operator Q , and operator Φ [14], which satisfy a commutation relationship $[\Phi, Q] = i\hbar$. And the contribution to the total Hamiltonian is given by $H_c = Q^2/(2C)$,

Figure 1: Schematic of the circuit under consideration

plus the energy due to the driving force $W_s = -I_s \Phi$.

In this paper, it is asserted that a quantum mechanically complete description of the interaction with the dissipative medium can be obtained in terms of the intrinsic electrical current operator, $\mathbf{J}_d(\mathbf{q}) = \sum_{\lambda\eta} \mathbf{p}^{\lambda\eta}(\mathbf{q}) C_\lambda^\dagger C_\eta$, with $\mathbf{p}^{\lambda\eta}(\mathbf{q}) = \sum_l \frac{e_l}{2mi} \int d^3r e^{-i\mathbf{q}\cdot\mathbf{r}} \{\phi_\lambda^*(\mathbf{r}) \nabla \phi_\eta(\mathbf{r}) - \phi_\eta(\mathbf{r}) \nabla \phi_\lambda^*(\mathbf{r})\}$; and the charge density operator (ρ_{cd}), $\rho_{cd}(\mathbf{r}) = \sum_l e_l \psi_d^\dagger(\mathbf{r}) \psi_d(\mathbf{r}) = \sum_i e_i \delta(\mathbf{r} - \mathbf{r}_i)$. Here ψ_d is the wave function of the dissipative medium, ϕ_η the basis states, and e_l the charge of the l^{th} specie. It can be shown [17] that in wavevector space the operators satisfy a commutation relationship $[\rho_{cd}(\mathbf{q}), \mathbf{J}_d(-\mathbf{q})] = \hbar \mathbf{q} \sum_l e_l^2/m$, where $\rho_{cd}(\mathbf{q}) = \int d^3r \rho_{cd}(\mathbf{r}) e^{-i\mathbf{q}\cdot\mathbf{r}}$. — — — — — <np2>

Construction of the Hamiltonian for the complete system started from the Hamiltonian for the current driven capacitor, and the interaction energies were derived using standard electromagnetic theory. The Hamiltonian was found to be

$$H = H_c + H_d + W_s + H_{je} + H_{cd} + W_d. \quad (1)$$

Here H_{cd} describes the interaction between the scalar potential Q/C and the charge density operator: $H_{cd} = -\int d^3r \rho_{cd}(\mathbf{r}) Q(\mathbf{r})/C$. And the energy H_{je} is due to the interaction between the current and field $H_{je} = \int d^3r \mathbf{J}_d(\mathbf{r}) \cdot \nabla \Phi(\mathbf{r})$. The interaction energy of the current source driving the resistor is given by the charge density interacting with the equivalent potential $W_d = -I_s R_s \rho_{cd}(\mathbf{q})$. The Hamiltonian for the dissipative medium is written as: $H_d = \sum_{\mathbf{k}\sigma} \mathcal{E}_{\mathbf{k}} C_{\mathbf{k}\sigma}^\dagger C_{\mathbf{k}\sigma} + V_{ol}^{-1} \sum_{\mathbf{q}} V_i(\mathbf{q}) \rho_i(\mathbf{q}) \rho_{cd}(\mathbf{q}) + H_{ee}$, where $(\rho_i(\mathbf{q}) = \sum_j e^{i\mathbf{q}\cdot\mathbf{R}_j})$ is the impurity density, $V_i(\mathbf{q})$ is the potential associated with the scattering, and H_{ee} is the electron-electron interaction. — — — — — <np3>

The total density matrix is written as $\rho_\Sigma(t) = S(t) \otimes \rho_d(t) + \rho_c(t)$, and it evolves according to the equation: $i\hbar \frac{\partial \rho_\Sigma}{\partial t} = [H, \rho_\Sigma]$. Here $S(t)$ is the reduced density matrix that describes the free particle $S(t) = Tr_d \rho_\Sigma(t)$, ρ_d describes the dissipative medium $\rho_d = Tr_s \rho_\Sigma(t)$, and ρ_c is the correlation between the sub-systems. In general, any density matrix can be written in the above form. The calculation is done in the interaction representation. Accordingly I write $H = H_0 + W + H_i$, with $H_0 = H_c + H_d$, and $W = W_s + W_d$, and of course for any operator O , $\tilde{O}(t) = e^{\frac{i}{\hbar} H_0 t} O e^{-\frac{i}{\hbar} H_0 t}$. It then follows from Liouville's equation that

$$i\hbar \frac{\partial \tilde{S}}{\partial t} = [\tilde{W}_s + \tilde{V}_s(t), \tilde{S}(t)] + Tr_d [\tilde{W}(t) + \tilde{H}_i(t), \tilde{\rho}_c(t)] \quad (2)$$

$$i\hbar \frac{\partial \tilde{\rho}_d}{\partial t} = [\tilde{W}_d + \tilde{V}_d(t), \tilde{\rho}_d(t)] + Tr_s [\tilde{W}(t) + \tilde{H}_i(t), \tilde{\rho}_c(t)] \quad (3)$$

$$i\hbar \frac{\partial \tilde{\rho}_c}{\partial t} = -[\tilde{V}_s(t) + \tilde{W}_s, \tilde{S}(t)] \otimes \tilde{\rho}_d - \tilde{S} \otimes [\tilde{V}_d(t) + \tilde{W}_d, \tilde{\rho}_d] + [\tilde{W} + \tilde{H}_i, \tilde{S} \otimes \tilde{\rho}_d] \\ + [\tilde{W} + \tilde{H}_i, \tilde{\rho}_c] - Tr_d \{[\tilde{W} + \tilde{H}_i, \tilde{\rho}_c]\} \otimes \tilde{\rho}_d - \tilde{S} \otimes Tr_s [\tilde{W} + \tilde{H}_i, \tilde{\rho}_c] \quad (4)$$

and $\tilde{V}_s(t) = Tr_d \{(\tilde{W}_d(t) + \tilde{H}_i(t)) \tilde{\rho}_d(t)\}$, with $\tilde{V}_d(t) = Tr_s \{(\tilde{W}_s(t) + \tilde{H}_i(t)) \tilde{S}(t)\}$.

A detailed description of the iterative process by which these coupled equations (2), (3) and (4) were solved will be described elsewhere [17]. First a solution for ρ_c was obtained (also via an iterative process), then that solution was substituted into (2); ρ_d was computed using the improved ρ_c , and $S(t)$. In computing $S(t)$, the initial values were obtained by assuming that initially S1 and S2 are open (see fig.1), and at $t=0$ the switches are closed, then the current turned on to a value of I_s . It was found that

$$\frac{\partial S}{\partial t} = \frac{1}{i\hbar} [H_c + W_s, S(t)] + \mathcal{U}_c \left(\frac{\partial \tilde{S}_a}{\partial t} + \frac{\partial \tilde{S}_b}{\partial t} \right) \mathcal{U}_c \quad (5)$$

with $\mathcal{U}_c = \exp(-iH_c t/\hbar)$ and,

$$\begin{aligned} \mathcal{U}_c \dot{\tilde{S}}_a \mathcal{U}_c \hbar^2 &= -[\Phi, \Phi S] W_J^+ + [\Phi, QS] W_{J1}^+ \frac{1}{C} - [Q, QS] W_\rho^+ \frac{1}{C^2} \\ &\quad + [\Phi, S\Phi] W_J^- - [\Phi, SQ] W_{J1}^- \frac{1}{C} + [Q, SQ] W_\rho^- \frac{1}{C^2} \\ \mathcal{U}_c \dot{\tilde{S}}_b \mathcal{U}_c \hbar^2 &= -([\Phi, [Q, S]] + [Q, [\Phi, S]]) \frac{1}{C} \text{Re}(W_{\rho J}^+) - ([Q, \{\Phi, S\}] - [\Phi, \{Q, S\}]) \frac{i}{C} \text{Im}(W_{\rho J}^+) \end{aligned}$$

The spectral densities of operators of the dissipative medium, and functions related to the spectral densities appear in equation (6). They are defined as follows: $W_J^+(T, t) = \int_0^t \text{Tr}_d \{ \rho_d(\tau) J_d^\dagger(\mathbf{q}, \tau) J_d(\mathbf{q}, 0) \} L_0^{-2} d\tau$; $W_{J1}^+(T, t) = \int_0^t \tau \text{Tr}_d \{ \rho_d(\tau) J_d^\dagger(\mathbf{q}, \tau) J_d(\mathbf{q}, 0) \} L_0^{-2} d\tau$; $W_\rho^+(T, t) = \int_0^t \text{Tr}_d \{ \rho_d(\tau) \rho_{cd}(\mathbf{q}, \tau) \rho_{cd}(-\mathbf{q}, 0) \} d\tau$. Other integrals of ensemble averages are similarly defined: $W_J^-(T, t) = \int_0^t < J_d^\dagger(\mathbf{q}, 0) J_d(\mathbf{q}, \tau) > d\tau L_0^{-2}$; $W_{J1}^-(T, t) = \int_0^t \tau < J_d^\dagger(\mathbf{q}, 0) J_d(\mathbf{q}, \tau) > d\tau L_0^{-2}$; and $W_\rho^-(T, t) = \int_0^t < \rho_{cd}(-\mathbf{q}, 0) \rho_{cd}(\mathbf{q}, \tau) > d\tau$. The integral of the cross-correlation function is given by $W_{\rho J}^+(T, t) = \int_0^t < \rho_{cd}(\mathbf{q}, \tau) J_d(\mathbf{q}, 0) > d\tau$.

In the second step, the solution for $S(t)$ is used in the computation of $\rho_d(t)$. Hence now $\tilde{V}_d(t) = Q_d \text{Tr}_s(QS(t))/C + (J_d - I_s) \text{Tr}_s(\Phi S(t))$, and from (3) it follows that

$$\begin{aligned} i\hbar \frac{\partial \tilde{\rho}_d}{\partial t} &= [\tilde{V}_d(t) + \tilde{W}_d(t), \tilde{\rho}_d(t)] + \frac{1}{i\hbar} \int_0^t dt' \text{Tr}_s [\tilde{H}_i(t), [\tilde{H}_i(t') + \tilde{W}_d(t'), \tilde{S}(t') \otimes \rho_d(t')]] \\ &\quad - \frac{1}{i\hbar} \int_0^t dt' \text{Tr}_s [\tilde{H}_i(t), \tilde{S}(t') \otimes [\tilde{V}_d(t'), \rho_d(t')]] \quad . \end{aligned} \quad (6)$$

The spectral density of J_d and related functions were evaluated from the relationship between the conductivity and the retarded current-current correlation ($\Pi_{\alpha\beta}$) function [18]:

$$\begin{aligned} \text{Re } \sigma_{\alpha\beta}(\mathbf{q}, \omega) &= - \text{Im } \Pi_{\alpha\beta}(\mathbf{q}, \omega)/\omega \\ \Pi_{\alpha\beta}(\mathbf{q}, \omega) &= -\frac{i}{V_{ol}} \int_{-\infty}^{\infty} dt \theta(t-t') e^{i\omega(t-t')} < \psi_d | [J_{d\alpha}^\dagger(\mathbf{q}, t), J_{d\beta}(\mathbf{q}, t')] | \psi_d > \end{aligned} \quad (7)$$

where $V_{ol} = L_0^3$ is the volume. The trace was taken with ($\rho_d(t) = \rho_d(0)$), and the ensemble averages were taken in the long wavelength limit ($\mathbf{q} \rightarrow 0$).

The spectral density of the charge fluctuation ($W_\rho^\pm$) in the resistor plays a critical role in determining the off diagonal elements of the density matrix. This charge fluctuation

is the fluctuation of the conjugate of the intrinsic current operator, and is not the charge fluctuation on the capacitor. The latter is determined mainly by the current fluctuation. Now the density-density correlation function is related to the *longitudinal* dielectric function [18]

$$\frac{1}{\epsilon_{\parallel}(\mathbf{q}, \omega)} = 1 - \lim_{i\omega_n \rightarrow \omega + i\delta} \frac{4\pi}{V_{ol} |\mathbf{q}|^2} \int_0^\beta d\tau e^{i\omega_n \tau} \langle T_\tau \rho_{cd}(\mathbf{q}, \tau) \rho_{cd}(-\mathbf{q}, 0) \rangle. \quad (8)$$

Evaluation of $W_\rho^+(T, t)$ would have been straightforward if the longitudinal f-sum rule ($\lim_{\mathbf{q} \rightarrow 0} \text{Im} \epsilon^{-1}(\mathbf{q}, \omega) = -\pi\omega_p[\delta(\omega - \omega_p) - \delta(\omega + \omega_p)]/2$) could have been utilized. But such is not the case since the low frequency variation of the integrand is important (see also (10) below). In the high temperature or semiclassical ($\hbar\beta\omega \ll 1$) limit we find $\lim_{\mathbf{q} \rightarrow 0} \langle \rho_{cd}(\mathbf{q}, \tau) \rho_{cd}(-\mathbf{q}, 0) \rangle = \hbar^2\beta e^{-t/\tau_m}/(4R_s\tau_m)$, and hence $W_\rho^+(T, t) = \hbar^2\beta(1 - e^{-t/\tau_m})/(4R_s)$. Here τ_m is the momentum relaxation time of the electron. --- <np4>

Hence, the Master equation for $S(t)$ can be written as

$$\begin{aligned} \frac{\partial S}{\partial t} = & \frac{1}{i\hbar} \left[\frac{1}{2C} Q^2 - I_s \Phi, S(t) \right] - [\Phi, [\Phi, S]] \frac{1}{\hbar^2} \text{Re}(W_J^+) + [\Phi, \{Q, S\}] \frac{i}{\hbar^2 C} \text{Im}(W_{J1}^+) \\ & - [Q, [Q, S]] \frac{1}{(\hbar C)^2} \text{Re}(W_\rho^+) + [\Phi, [Q, S]] \frac{1}{\hbar^2 C} \text{Re}(W_{J1}^+) \\ & - [\Phi, \{\Phi, S\}] \frac{i}{\hbar^2} \text{Im}(W_J^+) - [Q, \{Q, S\}] \frac{i}{(\hbar C)^2} \text{Im}(W_\rho^+) \\ & - (\hbar S + i(QS\Phi - \Phi SQ)) \frac{2}{\hbar^2 C} \text{Im}(W_{\rho J}^+) . \end{aligned} \quad (9)$$

It is worth noting that this equation is very clean: the coefficients of the various terms do not depend on (nor were they chosen to match) any classical/quantum criteria that is outside the scope of the Hamiltonian, and furthermore the coefficients are directly related to Green's functions of the current and charge density operators. There are more terms than expected. But more importantly, the physics contained in those terms is clear and fundamental. The terms proportional to $\text{Im}(W_\rho^+)$, and $\text{Im}(W_J^+)$ yield the change in the density matrix due to the change in the rest mass of the particle. Examination of $\text{Im}(W_J^+)$ shows that it is similar to the calculation of the renormalized mass of a free electron that is interacting with a radiation field.

The term $L_a = [Q, [Q, S]]\alpha_L$, has received a lot of attention, since supposedly it is required to preserve positivity of the density matrix [15], [16], [4], [2]. And despite significant efforts ([15], [4], [2]), the coefficient of that term has only been obtained at high temperature ($\alpha_L = \alpha_{L1}/(k_B T)$), thereby leaving the question of positivity still open at low temperatures. Furthermore the constant α_{L1} is not the same in the different works. It was shown by Lindblad that positivity of $\rho(t)$ is assured for Master equations of the Lax-Louisell form: $\dot{\rho} = -i\hbar^{-1}[H, \rho] + \sum_j ([A_j^\dagger, \rho A_j] + H.C)$ (where A_j is composed of system operators). Under the conditions implicitly considered by the aforementioned investigators (high temperature and the dissipative medium is not quantized), equation

(9) is of the Lax-Louisell form. Under all conditions equation (5) is of the Lax-Louisell form, and (9) would have been of that form if terms proportional to the real part of the cross correlation were kept. However when the correlation functions are computed for the dissipative medium in equilibrium, then $\text{Re}W_{\rho J}^+ = 0$. If the dissipative medium is driven very far from equilibrium then the aforementioned terms can be reinserted, and the $\text{Re}W_{\rho J}^+$ computed using equation (12). The really astonishing result concerning L_a that is reported here is that the coefficient (α_L) is related to an important physical quantity: the longitudinal dielectric function (or the density susceptibility function when the system operators are position and momentum). Hence with (8) it is now possible to give an exact expression for (α_L), that is valid at all temperatures:

$$\text{Re}(W_{\rho}^+(t)) = -\frac{\hbar}{(2\pi)^2}V_{ol} \lim_{\mathbf{q} \rightarrow 0} \int_{-\infty}^{\infty} \frac{|\mathbf{q}|^2}{1 - e^{-\beta\hbar\omega}} \text{Im} \left(\frac{1}{\epsilon_{\parallel}(\mathbf{q}, \omega)} \right) \frac{\sin(\omega t)}{\omega} d\omega \quad . \quad (10)$$

The physical mechanism associated with L_a is the screening of coherent charge fluctuation (on the capacitor) by the medium. One can say that the friction ($R(\omega)$) damps the ensemble-averaged charge/momentum, while the coherent momentum fluctuation is damped by the density susceptibility.

In a semiclassical computation, the diagonal elements $\langle u|S|u \rangle$ can be treated as a quasiprobability distribution, here $|u \rangle$ is the eigenvector of the charge $Q|u \rangle = u|u \rangle$. The term L_a does not affect evolution of the diagonal elements. From (9), the evolution of $\langle u|\dot{S}|u \rangle$ is given by a Fokker-Planck equation, with a probability diffusion coefficient $D_{uu} = \text{Re}(W_J^+)$. In the purely ohmic limit ($\tau_m \rightarrow \delta$), $D_{uu} \simeq K_B T/R_s + \hbar/(\pi R_s t)$, and hence for all times $t < \hbar\beta/\pi$, the diffusion and particle's evolution are purely quantum mechanical. Evolution of the ensemble average $\langle Q \rangle \equiv \text{Tr}\{QS(t)\}$, is given by

$$\frac{d\langle Q \rangle}{dt} - \frac{2}{\hbar C} \text{Im}(W_{J1}^+) \langle Q \rangle = I_s \quad (11)$$

which reduces to the classical equation: $\dot{Q} + (R_s C)^{-1}Q = I_s$. Equation (11) represents a true milestone: the derivation —for the first time— of the classical equation that describe a dissipative system from a purely quantum theory. Note that W_{J1}^+ is directly related to ψ_d , the wavefunction of the dissipative medium. In theories that use a collection of harmonic oscillators, the classical equation is not derived, but rather it is used to fit the free parameters (spectrum, etc) of the theory. — — — <np5>

It is now possible to write —for the first time— a reduced density matrix that describes the evolution of a dissipative medium that is coupled to a quantum object. Continuing from (6), I obtain:

$$\begin{aligned} \frac{\partial \rho_d}{\partial t} = & \frac{1}{i\hbar} [H_d + W_d + V_d, \rho_d] - [I_d, [I_d, \rho_d]] \frac{1}{\hbar^2} \text{Re} W_{\Phi\Phi}^+(t) \\ & + ([Q_d, \{I_d, \rho_d\}] - [I_d, \{Q_d, \rho_d\}]) \frac{i}{\hbar^2} \text{Im} W_{Q\Phi}^+(t) - [Q_d, [Q_d, \rho_d]] \frac{1}{\hbar^2} W_{QQ}^+(t) \\ & + [I_d, \{I_d, \rho_d\}] \frac{i}{\hbar^2} \text{Im} W_{\Phi\Phi}^+(t) \quad . \end{aligned} \quad (12)$$

The charge operator associated with the charge density is defined as: $Q_d = \lim_{\mathbf{q} \rightarrow 0} \rho_{cd}(\mathbf{q})$, and I_d (amps) is the long wavelength limit of the current through the resistor. In this bistratum quantization approach, one set of operators describe the individual modes or individual particles of the dissipative medium (C'_λ s, see numbered paragraph 2 (or < np2 >)), while the key operators that describe the coupling and enter the Master equations 1) satisfy a commutation relationship in wavevector space, and 2) are composed of the microscopic operators. Equation (12) still contains the full H_d and hence a direct solution is far from trivial. Nonetheless, the equation is manageable because the results of the equilibrium (only H_d) solution are known. The partial spectral functions are given by:

$$W_{\Lambda_i \Lambda_j}^+(T, t) = \int_0^t dt' \text{Tr}_s(S(t') \Lambda_i(t - t') \Lambda_j) - \text{Tr}_s(S(t') \Lambda_j) \text{Tr}_s(S(t') \Lambda_i(t - t'))$$

with $\Lambda_1 = \Phi$, and $\Lambda_2 = Q/C$.

Equations (9) and (12) radiate the sublime grace of the new method: bistratum quantization, in concert with a coupled systems approach that recognizes both objects as quantum entities. The foundation of theories of dissipative quantum systems has so far been inscrutable. In contrast, here the quantization of the medium, quantization of the operators used to construct the interaction Hamiltonian, and the fundamental connection between those operators and the microscopic operators are all clear. Parenthetically, it is possible to draw a distinction between an open system (typically found in quantum optics), and an inherently dissipative system. In an open system such as an atom in a cavity, a process such as spontaneous emission is sometimes viewed as dissipative, but if the number of modes is reduced then the process becomes reversible. In contrast, resistance to even dc current flow, and irreversibility is present in the typical closed system. The difference is due to the underlying mechanisms in the dissipative medium: in one case a set of independent modes, and in the other a strongly coupled (H_{ee}) electron system. It is important to note that an intrinsically dissipative medium is not really quantized in models that employ a collection of oscillators (or similar). One may think that under the quantization of the harmonic oscillators, ... but quantization in a space is irreducible, there is nothing under, under. A direct consequence being that the evolution of the dissipative medium could not be determined, and hence questions concerning operators of that medium were part of the unspeakable.

In summary, equations for the reduced density matrices of two interacting sub-systems, a free particle and a linearly dissipative medium, were derived. The approach to the 40 year conundrum (see < np1 >) of a Hamiltonian description of the interacting sub-systems, and quantizing the whole system is clear. Operators that satisfy a commutation relation—in wavevector space— were utilized to construct an interaction Hamiltonian. The total density matrix was written as a tensor product of the reduced density matrices plus a correlation matrix. Partial spectral densities that appear in the Master equation for the particle are given in terms of well known quantities: the retarded current-current

correlation function, and the retarded density-density correlation function.

The theory is particularly important because a) in many cases of interest, operators belonging to the dissipative medium carry the required information and now questions that contain those operators can be answered, and b) it appears to be the basis of a truly quantum circuit theory. For example, in the system shown in figure 1 (which may be part of a larger circuit), the mean current through the resistor, and the fluctuation of that current often correspond to the detected signal and the fluctuation of the signal. A circuit theory that can describe quantum transport is particularly important these days, because everybody's vision of the future *now* includes nanoscale and macroscopic quantum circuits.

One of the most surprising features of Brownian motion that was unveiled in this investigation is the role played by the longitudinal dielectric function. It is easy to understand why all previous investigations have missed this important feature. Classical and semiclassical studies are based primarily on the Langevin, or quantum Langevin equation (for the momentum), and as can be ascertained from $\langle np5 \rangle$, the density correlation does not contribute to the Langevin noise force. Quantum studies were based on reproducing the friction constant $R(\omega)$, either directly through the Caldeira-Leggett model, or indirectly through a fluctuating force and the fluctuation-dissipation theorem. However as we have seen the dynamics of the medium is underdetermined by $R(\omega)$, or the associated fluctuation-dissipation theorem. How reliable are seemingly exact quantum models of an object, where exactness is determined by some classical criteria? It appears that a quantum object can only be known via the correct Hamiltonian.
